## Abstract

Climate is a main driver of species distributions, but all species are not equally affected by climate change, and their differential responses to similar climatic constraints might dramatically affect the local species composition. In the context of climate warming, a better knowledge of the ability of dispersal-limited and habitat-specialist species to track climate change at local scale is urgently needed. Comparing the population genetic and demographic impacts of past climate cycles in multiple co-distributed species with similar ecological requirements help predicting the community-scale response to climate warming, but such comparative studies remain rare. Here, we studied the relationship between demographic history and past changes in spatial distribution of three protected peatland butterfly species (*Boloria aquilonaris*, *Coenonympha tullia*, *Lycaena helle*) in the Jura massif (France), using a genomic approach (ddRAD sequencing) and species distribution modeling (SDM). We found a similar and narrow thermal niche among species, and shared demographic histories of post-glacial decline and recent fragmentation of populations. Each species functions as a single metapopulation at the regional scale, with a North-South gradient of decreasing genetic diversity that fits the local dynamics of the ice cover over time. However, we found no correlation between changes in the quantity or the quality of suitable areas and changes in effective population size over time. This suggests that species ranges moved beyond the Jura massif during the less favorable climatic periods, and/or that habitat loss and deterioration are major drivers of the current dramatic decline observed in the three species. Our findings allow better understanding how history events and contemporary dynamics shape local biodiversity, providing valuable knowledge to identify appropriate conservation strategies.

**Keywords:** Comparative population genomics – Species distribution modeling – Genetic diversity – Demographic inference – Climate change – ddRAD sequencing

## 1. Introduction

Climate has major effects on the global distribution of species, but all species are not equally vulnerable to climate change. The variety of responses is the result of differences in species biology and ecology (dispersal behavior, niche characteristics and niche breadth, physiology, phenology) together with historical contingencies (Estrada et al., 2018; Pedreschi et al., 2019). For example, butterflies were shown to be more vulnerable to climate change than birds (Devictor et al., 2012) and within butterflies, habitat specialist species generally appear to be more at risk than generalist species (Warren et al., 2001; Settele et al., 2008; Heikkinen et al., 2010; Noreika et al., 2016). In fact, habitat specialization and sedentary behavior might have negatively affected the altitudinal shift response to recent past climate change among butterfly species (Habel et al., 2023). Furthermore, in contrast to several organisms that have already shown range shifts northwards as a response to ongoing climate warming (Parmesan et al., 1999; Devictor et al., 2012), southern populations of post-glacial relict species are often trapped in isolated altitudinal habitats (Turlure et al., 2010). Given the current rate of warming, we need to evaluate the ability of dispersal-limited and habitat specialist species to track their climate niches at local scale.

The population genetic and distributional responses of species to past climate changes can give insight on their capacity to cope with ongoing warming. The Pleistocene climatic fluctuations have profoundly impacted species distributions (Hewitt, 2000; Schmitt, 2007). During the last glacial maximum (LGM), many temperate species from Europe showed range contraction towards glacial refuges in Mediterranean peninsulas where the climate remained suitable (Taberlet et al., 1998; Hewitt, 2000, 2004). However, the picture is less clear for boreo-montane species (Schmitt and Varga, 2012). Some species may have survived the last glaciation in restricted non-glaciated areas at high latitude or altitude, or as small populations at the margin of the glaciated areas (Schoville et al., 2011; Sherpa et al., 2022). Other species may have

benefited from cold temperature and expanded their range during the LGM (Kebaïli et al., 2022). These different distributional responses of boreo-montane species are expected to result in distinct population demographic histories; for instance, a decrease in effective population size ( $N_e$ ) during the LGM for species that remained within small ice-free refuges (Sherpa et al., 2022), or an increase in  $N_e$  for cold-adapted species that expanded during the LGM and reduced  $N_e$  during interglacial periods (Kebaïli et al., 2022). The current genetic diversity of populations should reflect, in part, their demographic and biogeographic history, with decreasing genetic diversity from the glacial refuge to the newly colonized areas (Hewitt 2004). However, very few studies have investigated the relationship between habitat suitability and demographic changes over time, and how currently co-distributed species with similar ecology did respond to past climate change.

The boreo-montane species *Boloria aquilonaris* (Nymphalidae, Heliconinae), *Coenonympha tullia* (Nymphalidae, Satyrinae) and *Lycaena helle* (Lycaenidae) have a patchy distribution in Europe and are among the most endangered European butterflies (van Swaay et al., 2011). The main causes of the recent decline of these peatland species are land-use changes (peat exploitation, drainage of wetlands and conversion to crop production or urbanization) and climate change (Settele et al., 2008; Noreika et al., 2016). The three species benefit from a high protection status both at the Europe and local scales, and a large amount of literature is available on their current distribution, local habitat requirements and population ecology through conservation monitoring programs (Settele et al., 2008; Turlure et al., 2010; Habel et al., 2011; Fisher et al., 2014; Weking et al., 2013, Noreika et al., 2016; Čelik et al., 2018; Lebigre et al., 2022; Osborne et al., 2022). Yet little is known about their evolutionary history and past distributions (but see Habel et al., 2010 for *L. helle*). Given that these peatland butterflies have a similar habitat, they might show an analogous demographic history of population decline concomitant with periods of habitat contraction. However, habitat quality rather than habitat

quantity might be a better predictor of local abundance, especially for habitat specialists such as peatland butterflies (Dennis and Eales, 1997; Noreika et al., 2016; Čelik et al., 2018; Lebigre et al., 2022). Furthermore, the three species differ in several life-history traits including larval host-plant, overwintering stages and microhabitat (Settele et al., 2008), which might result in slight differences in climatic niches and responses to climate change, and therefore in population histories.

Here, we ask whether habitat specialists such as peatland butterflies, which are co-distributed in the Jura massif but have distinct life-history traits, have a common demographic and biogeographic history in response to the climate changes during the last glacial cycle. Contrary to the Alps, the Jura massif has never been entirely covered by ice during the LGM (Lhosmot et al., 2022) and might have acted as a refuge for cold-adapted species, possibly in multiple distinct areas. This hypothesis has however hardly been tested so far (Sherpa et al., 2022). Combining fine-scale population genomics (Jura massif) and coarse-scale predictions of species distribution (Europe), we specifically address the following questions: (1) Do the three species present the same population genetic structure and a shared demographic history in the Jura massif? (2) Is their current distribution explained by the same climatic predictors? (3) How did the spatial distribution of favorable areas change over time for each species, and has the Jura massif always been a suitable area? (4) Is there a relationship between the effective population size and the quantity and/or the quality of climatically suitable areas in Europe and Jura since the last interglacial (LIG)?

## **2. Material and Methods**

### **2.1 Studied species**

In the Jura massif, the three species are univoltine and on-wing in May-June. They all are small butterflies with limited dispersal found in wetlands, but they differ in their larval-host plant,

overwintering stages and microhabitat. The Cranberry Fritillary *B. aquilonaris* is found in raised bogs (European Nature Information System (EUNIS) code: D1.1; <https://www.eea.europa.eu/data-and-maps/data/eunis-habitat-classification-1>) and wet heaths, in sheltered places at the edges of woods or in clearings. Eggs are laid on *Vaccinium oxycoccos*, the larval host-plant, but the caterpillar overwinters in the moss layer just after hatching and starts feeding only the following year: the summer thermal buffering of the *Sphagnum* hummocks appear to be as important as the presence of the host plant for larval survival (Settele et al., 2008; Turlure et al., 2010). The Violet Copper *L. helle* lives in moist or wet eutrophic and mesotrophic grasslands (EUNIS code: 3.4) and uses *Bistorta officinalis* as larval foodplant, and overwinters as a pupa (Habel et al., 2011; Fisher et al., 2014). *Lycaena helle* dispersal is limited by both forests and fully open habitats as this butterfly prefers wind-sheltered stands (Fischer et al., 1999; Bauerfeind et al., 2009; Chuluunbaatar et al., 2009; Lebigre, 2022). The Large Heath *C. tullia* is a specialist of good-quality lowland fens with water table at or just below the surface (Lebigre et al., 2022), typically found in poor fens and soft-water spring mires (EUNIS code: D2.2). Unlike the two other species, the caterpillar can feed on many different grasses (Clarke, 2022) but it feeds on *Carex* sp. in limestone Jura Mountains (Decoin et al., 2021). The third instar caterpillars hibernate in the tussocks of the foodplant and actively escape from flooding by climbing up so that winter vegetation structure is a major constrain for this species (Joy and Pullin, 1997; Weking et al., 2013; Čelik et al., 2018; Osborne et al., 2022).

## 2.2 Study area and sample collection

The study area covers the Jura massif, on the border between France and Switzerland (Figure 1). Sampling localities were distributed into three main geographical regions in France: Haut-Jura (HJ); Doubs and Dugeon valleys (DDV); plateau of Russey (RUS) (Figure 1; Supplementary Table S1). The sampling was performed by qualified personnel from:

Conservatoire Botanique Nationale de Franche-Comté – Observatoire des Invertébrés (CBNFC–ORI); Conservatoire d'Espaces Naturels de Franche-Comté (CEN FC); Réserve Naturelle du Lac de Remoray; Établissement Public d'Aménagement et de Gestion de l'Eau Haut-Doubs Haute-Loue (EPAGE HDHL); Parc naturel régional du Haut-Jura (PNRHJ). The experimental protocols were validated by the French authorities (authorization number: DDPP01-21-052) and by the Swiss Canton of Vaud authorities (authorization number: 2021-3539). For each locality, one to nine butterflies were captured using hand-nets, and one hind leg was collected before immediate release. This method was shown to cause low disturbance on post-release flight behavior and survival in butterflies (Koscinski et al., 2011), thus minimizing the impact of sampling on vulnerable populations of protected species. We sampled 52 individuals from 11 localities for *B. aquilonaris*, 100 individuals from 18 localities for *C. tullia* and 236 individuals from 67 localities for *L. helle*. For *L. helle*, two additional localities were sampled in the Canton de Vaud, Switzerland (Supplementary Table S1). The sampling was performed during the flight period in 2018, 2020 and 2021. Collected tissues were stored at -20°C until DNA extraction.

### 2.3 DNA extraction and ddRAD-seq libraries preparation

DNA was extracted (DNEasy Blood & Tissue kit, Qiagen) and 50 ng was double-digested with *SbfI*-HF and *MspI* restriction enzymes (New England Biolabs) and individually tagged during ligation to P1 and P2 adapters as described in Kebaïli et al. (2021). After a first purification step with 1.5 volumes of NucleoMag NGS Clean-up and Size Selected (Macherey-Nagel SAS), the adapters-ligated DNA fragments were size-selected for a length of 200–600 bp (Pippin-Prep 2% gel cassette; Sage Science Inc). Libraries were amplified in 10 independent replicates, which were pooled and purified with 1 volume of NucleoMag NGS Clean-up and Size Selected (Macherey-Nagel SAS) (see Kebaïli et al., 2022 for PCR conditions). The libraries were

sequenced on Illumina HiSeq 2500 ( $2 \times 125\text{bp}$ ) in 2018 and Illumina NovaSeq 6000 ( $2 \times 150\text{bp}$ ) in 2020 and 2021.

## 2.4 Genomic data treatment

After trimming adapters (BBDuk from the BBTools package; Bushnell, 2014), the assembly of ddRAD loci and SNP calling were performed using the Stacks v2.2 *de novo* pipeline (Rochette et al., 2019). Reads were demultiplexed, filtered based on quality and cut to 110bp (*process\_radtags*). Loci reconstruction was performed for each species separately, using a maximum of eight mismatches to merge two stacks into a polymorphic locus within an individual (*ustacks*) and between individuals (*cstacks*). Single-end catalog loci (*sstacks*) were merged into single loci (*gstacks*) and SNP datasets included all biallelic variant positions (*populations*).

SNPs were filtered using VCFtools v1.16 (Danecek et al., 2011), following a modified approach of the one proposed by O’Leary et al. (2018). We removed SNPs with read coverage  $\leq 5X$  and mean read coverage among individuals  $\leq 15X$ . To minimize the amount of missing data in final datasets ( $< 15\%$ ), we discarded individuals with high percentage of missing data: six for *B. aquilonaris*; thirteen for *C. tullia*; eighteen for *L. helle* (Supplementary Table S2). To maximize the number of SNPs, we applied different filtering parameters for each species, retaining SNPs with  $< 30\%$  missing data for *C. tullia* and *L. helle*, and SNPs with  $< 50\%$  missing data for *B. aquilonaris*. Finally, we retained one random SNP per locus.

## 2.5 Genetic diversity and population structure

Population genetic structure and diversity analyses were performed after filtering the SNP datasets for low frequency variants (minor allele frequency,  $\text{MAF} \leq 1\%$ ). We first inferred individual ancestry coefficients using the program ADMIXTURE v1.3 (Alexander et al., 2009).

The optimal number of K genetic clusters was determined based on the lowest error rate from a 10-fold cross-validation (CVE). To evaluate the level of genetic differentiation between sampling localities, we calculated pairwise  $F_{ST}$  using the *hierfstat* package v0.5-10 (Goudet, 2005) in R (R Core Team, 2022).

The *hierfstat* R package was also used to calculate population genetic diversity, including observed heterozygosity ( $H_o$ ), expected heterozygosity ( $H_e$ ), inbreeding coefficient ( $F_{IS}$ ), and differentiation between a given locality and all the localities in the study area (population-specific  $F_{ST}$ ). For  $H_o$ ,  $H_e$  and  $F_{IS}$ , 95% confidence intervals (CI95) were estimated from 1,000 bootstraps of the data, and 100 bootstraps for the population-specific  $F_{ST}$ . Spatial patterns of genetic diversity were inferred using the program EEMS (Petkova et al., 2016). We computed genetic dissimilarities on a spatial grid of 600 demes for each species. The analysis was repeated independently three times, with 4,000,000 MCMC iterations, a burn-in of 1,000,000 and a thinning interval of 10,000. The average posterior distributions of within-deme genetic variability were represented on maps using the *rEEMSplots* R package (Petkova et al., 2016).

## 2.6 Climate niche models

To determine the best climatic predictors of the distribution of each of the three species at the European scale, we performed species distribution models (SDMs) using the *biomod2* R package v4.2.2 (Thuiller et al., 2016). Species presences were extracted from the Global Biodiversity Information Facility database (GBIF, 2022). We selected human observations after 1970 with coordinate precision < 5 km. We added the geo-reference of all our sampling localities (Supplementary Table S1) and of local managers population monitoring data recorded after 1970. In total, we obtained 11,432 occurrences for *B. aquilonaris*, 16,106 for *C. tullia* and 4,932 for *L. helle*. To reduce sampling bias, one occurrence was randomly selected within a

1 raster cell of 1 km (Fourcade et al., 2014), resulting in 2,944, 1,515 and 603 occurrences,  
2 respectively. We selected six bioclimatic variables for 1970–2000 from the WorldClim  
3 database v2.1 (2.5 arc-minutes; Fick and Hijmans, 2017) that were shown to be important  
4 predictors for another co-distributed butterfly (Sherpa et al., 2022): mean annual temperature  
5 (BIO1); mean diurnal range (BIO2); isothermality (BIO3); mean temperature of the wettest  
6 quarter (BIO8); annual precipitation (BIO12); precipitation seasonality (BIO15).

SDMs included five statistical models: generalized linear (GLM), additive (GAM), and  
boosting (GBM) models; maximum entropy (MAXENT); random forest (RF) (Araújo and  
New, 2007; Marmion et al., 2009). A dataset of 10,000 random pseudo-absences was produced  
using a surface range envelope model. Training data included 70% of the occurrences randomly  
sampled, and the remaining 30% were used to evaluate model performance with two metrics:  
the true skill statistic (TSS) and the area under the curve (AUC). We performed a three-fold  
internal cross-validation, resulting in a total of 45 models that were merged using the weighted  
sum of probabilities (EMwmeanByTSS) or the committee averaging (EMcaByTSS) methods.  
For each bioclimatic variable, we calculated the importance of its contribution to the model (see  
Thuiller et al., 2009) and variable importance was normalized to the model for comparison  
among species.

## 2.7 Demographic inferences

Changes in effective population size ( $N_e$ ) over time were inferred using the Stairway Plot  
method v2 (Liu and Fu, 2020) based on the site frequency spectrum (SFS). The SFS was  
calculated from all SNP positions (no filter on MAF) and imputed genotypes. Missing data was  
imputed to the most likely genotype using the LEA R package v3.0.0 (*impute* function; Frichot  
et al., 2014), and a number of ancestral populations corresponding to the number of  
geographical areas:  $N = 5$  for *B. aquilonaris* and *C. tullia*;  $N = 8$  for *L. helle* (Supplementary

Table S1). We used a mutation rate of  $2.10^{-9}$  based on previous studies in butterflies (Keightley et al., 2015; Kebaili et al., 2022; Sherpa et al., 2022) and a generation time of one year, all species being univoltine. The total sequence length accounted for both polymorphic and monomorphic loci. Two-epoch models were built with 67% of segregating sites used for training and break points following authors' recommendation. Median estimates of  $N_e$  and  $CI_{95}$  were obtained from 200 bootstrap replicates. Stairway Plot analyses were carried out at: (1) the population level based on population genetics results; (2) the species level including all 48 individuals for *B. aquilonaris* and down-sampling randomly the *C. tullia* and *L. helle* datasets to the same sample size.

Divergence times between the three main geographical areas (HJ, DDV, and RUS) were inferred using DIYABC v2.1.0 (Cornuet et al., 2014), using the SNP datasets of 48 individuals filtered for  $MAF \leq 1\%$ . Two series of analyses determined the time period and mode of divergence. The first analyses compared three scenarios of synchronous divergence: (1) during an ancient decrease in  $N_e$  (Split-1D); (2) during a recent decrease in  $N_e$  (Split-2D); (3) during an ancient increase in  $N_e$  (Split-Exp) (Supplementary Table S3). The second analyses compared: (1) synchronous divergence times (Synch-Split); (2) an early divergence of RUS followed by HJ and DDV (Asynch-Split1); (3) an early divergence of HJ followed by RUS and DDV (Asynch-Split2) (Supplementary Table S3). We ran 100,000 simulations for each scenario, using the mean genetic diversities within populations,  $F_{ST}$  and Nei's distances among populations as summary statistics. The 1% of simulated data closest to the observed data were used to calculate the posterior probabilities of scenarios (logistic regression) and the posterior distribution of demographic parameters. Confidence in scenario choice (Type I and Type II errors) was evaluated from 100 newly simulated datasets.

## 2.8 Changes in potential distribution and species demography over time

To characterize the changes in species potential distribution over time, we projected SDMs into current climate (1970–2000) and eight palaeoclimates: Late Holocene (LatH: 0.3–4.2 kya); Mid Holocene (MidH: 4.2–8.3 kya); Early Holocene (EarH: 8.3–11.7 kya); Younger Dryas Stadial (YDS: 11.7–12.9 kya); Bølling-Allerød (BA: 12.9–14.7 kya); Heinrich Stadial 1 (HS: 14.7–17.0 kya); Last Glacial Maximum (LGM: ca. 21 kya); Last Interglacial (LIG: ca. 130 kya). Palaeoclimate data was retrieved from the PaleoClim database (2.5 arc-minutes; Brown et al., 2018; Karger et al., 2020). Palaeoclimate projections were resampled to a 1×1 km resolution, using the k-nearest neighbors method in QGIS v3.22.3 (QGIS Development Team, 2022).

The availability of suitable habitats at each of the nine time periods was characterized by two metrics. First, we calculated the average predicted probability of presence (pp) across all cells (hereinafter habitat quality). Second, we used the pp threshold that maximizes the TSS score (ppTSS) for each species model and calculated the total area with predicted presence: pp > ppTSS (hereinafter habitat quantity). These two metrics were calculated at the European scale as well as at the scale of the Jura massif, by working on the geographic subset of SDM projections corresponding to the massif. Raster manipulation and indices were calculated using QGIS. To evaluate the impact of past climate fluctuations on the species demography history, we combined our results of climate niche and demographic models. We tested the relationship between changes in habitat quality and habitat quantity over time, and changes in Ne over time. For a given time period, the Ne corresponded to the mean of the inferred median Ne in this period based on species demographic history (all populations combined) using the Stairway Plot method. The relationships between Ne and habitat metrics, both at European and Jura massif scales, were tested using Spearman correlations in R.

### 3. Results

#### 3.1 Genetic datasets

We obtained an average of  $0.46 \pm 0.28$  (SD; standard deviation) million reads per individual for *B. aquilonaris* (Ba),  $0.56 \pm 0.46$  million reads for *C. tullia* (Ct) and  $0.78 \pm 0.79$  million reads for *L. helle* (Lh) after quality filtering (Supplementary Table S2). After dropping individuals with a high proportion of missing data, the final sample sizes (N) for the three species were  $N_{Ba} = 48$ ,  $N_{Ct} = 87$  and  $N_{Lh} = 218$ . After applying the missing data and physical linkage filters, the number of loci was 380 for *B. aquilonaris*, 1,305 for *C. tullia* and 1,569 for *L. helle*, which were used for Stairway Plot analyses. After filtering for low frequency variants, the datasets included 380 SNPs for *B. aquilonaris*, 1,293 SNPs for *C. tullia* and 1,455 SNPs for *L. helle*, which were used for population structure and diversity analyses, and divergence time estimations (DIYABC). The average percentage of missing data among individuals per locus was  $10.76 \pm 7.97$  for *B. aquilonaris*,  $12.44 \pm 8.85$  for *C. tullia* and  $11.78 \pm 7.77$  for *L. helle* (Supplementary Table S2).

### 3.2 Population genetic structure and diversity

The level of population differentiation in the Jura massif varied among species. The optimal number of genetic clusters from ADMIXTURE analysis was  $K = 1$  for *B. aquilonaris* and *C. tullia*, and  $K = 3$  for *L. helle* (Supplementary Figure S1). Investigating higher values of  $K$  did not reveal a clear geographic structuring for *B. aquilonaris* (Figure 3; Supplementary Figure S2). For  $K = 3$  genetic groups, the two southern localities of the HJ region (mainly dark red cluster) differentiated from the four northern localities of the RUS region (mainly orange cluster). However, most localities showed a high number of admixed individuals. For *C. tullia*, all localities in the RUS region showed genetic differentiation with those of the HJ and DDV regions for  $K = 2$ , and these two last regions were further separated for  $K = 3$  (Figure 3; Supplementary Figure S3). For *L. helle*, the optimal number of  $K = 3$  groups revealed population structure largely corresponding to the three geographical regions but with substantial

admixture (Figure 3; Supplementary Figure S4). Increasing K up to 6 further separated localities from the HJ and DDV regions according to their geography, with three areas in HJ: southern HJ, Northern HJ and Grandvaux-Malvaux; two areas in DDV: Haut-Doubs and Dugeon basin (Figure 3; Supplementary Table S1).

The three regions exhibited different spatial patterns of genetic diversity. The HJ region was the less genetically diversified in all the three species, and the RUS region had the highest diversity for *B. aquilonaris* and *C. tullia* but it was the DDV region for *L. helle* (Figure 2A; Table 1). In accordance, significant spatial genetic dissimilarities were detected for *B. aquilonaris* and *C. tullia*, with a decreasing gradient of diversity from North to South, whereas *L. helle* rather showed a diverse population in the center of the study area and a reduction of diversity at extreme North and South localities (Figure 2B).

For most regions, the distribution of heterozygosity (observed,  $H_o$ ; expected,  $H_e$ ) was bimodal, indicating two groups of localities: a group with a high genetic diversity and a group with a lower genetic diversity (Figure 2A). This pattern is typical of a metapopulation system, with some well-connected and highly diversified localities corresponding to the core (or source) population, and more isolated (sink) populations suffering from drift and genetic erosion. Accordingly, population-specific  $F_{ST}$  were significantly positive (indicative of the effect of genetic drift) for all localities in all regions but lower in the most diverse regions for *C. tullia* (RUS) and for *L. helle* (DDV) (Table 1). Another indication of a dynamic, non-equilibrium, metapopulation functioning in the three species is the significantly positive inbreeding coefficient  $F_{IS}$  observed in all localities, which is especially high in *C. tullia* (Table 1). The average pairwise  $F_{ST}$  among localities within regions revealed spatial variation in the level of population differentiation. In *B. aquilonaris*, the most diversified RUS region showed the lowest genetic differentiation among localities ( $F_{ST} = 0.085 \pm 0.05$ ) compared to differentiation within HJ ( $F_{ST} = 0.227 \pm 0.04$ ) and within DDV ( $F_{ST} = 0.199 \pm 0.03$ ) (Supplementary Table

S5). For the two other species, the localities within the DDV region were the less differentiated, with an average pairwise  $F_{ST} = 0.067 \pm 0.04$  compared to the HJ ( $F_{ST} = 0.111 \pm 0.07$ ) and RUS ( $F_{ST} = 0.116 \pm 0.06$ ) regions in *C. tullia* and  $F_{ST} = 0.048 \pm 0.04$  compared to the HJ ( $F_{ST} = 0.116 \pm 0.06$ ) and RUS ( $F_{ST} = 0.096 \pm 0.08$ ) in *L. helle* (Supplementary Tables S6 and S7).

### 3.3 Species demographic history

The demographic history of populations in the Jura massif revealed consistent patterns among the three regions and for the three species (Supplementary Figure S5). Given the metapopulation functioning of each species suggested by population structure and diversity analyses, we inferred the changes in effective population size ( $N_e$ ) over time at the species level including individuals from all the three regions (Figure 4A). Two species (*C. tullia* and *L. helle*) showed an ancient demographic expansion, with an increase in  $N_e$  between 1 Mya and 200 kya. All species showed a relatively recent decrease in  $N_e$ , which started during the last glacial period (approximately 25 kya) for *B. aquilonaris* and *L. helle*, and more recently (6 kya) for *C. tullia*.

The three species showed similar time and mode of divergence between regions in the Jura massif (Figure 4B). For the first DIYABC analysis testing the period of divergence (ancient vs. recent), the most likely scenario was a recent split between the HJ, RUS and DDV regions (scenario Split-2D; Table 2). For the second DIYABC analysis testing the mode of divergence (synchronous vs. asynchronous), the most likely scenario was a first divergence of the RUS region, followed by the divergence between the southern regions DDV and HJ (scenario Asynch-Split2; Table 2). The first population split (S1) occurred during Mid Holocene (7.0 kya) for *C. tullia* and *L. helle* and more recently during Late Holocene (2.1 kya) for *B. aquilonaris* (Figures 4C; Supplementary Table S8). The second split (S2) was estimated during the Late Holocene, approximately 1.4 kya, 0.8 kya and 2.6 kya for *B. aquilonaris*, *C. tullia* and

*L. helle*, respectively. While the S1 split is subsequent to the ancient decrease (D1) in  $N_e$  in the ancestral populations (no overlap between S1 and D1), the S2 split occurred at the same time as the more recent decrease (D2) in  $N_e$  (overlap between S2, D2R and D2HD).

### 3.4 Species current climate distribution

Species distribution model (SDM) evaluation statistics revealed a good performance of all models on average for *B. aquilonaris* (TSS = 0.72; AUC = 0.94), *C. tullia* (TSS = 0.85; AUC = 0.98) and *L. helle* (TSS = 0.82; AUC = 0.97). The main climatic predictor of the current distribution of the three species was the mean annual temperature (BIO1; > 40%, Table 3). At the European scale, the thermal niche of the three species was extremely narrow and at their highest limit in the Jura massif (Table 3), *L. helle* being the most narrow-range and thermophilic species with a BIO1 range excluding negative temperatures. Isothermality (BIO3) and precipitation seasonality (BIO15) were also two important predictors of the three species distribution, while total annual precipitation (BIO12) was the least important predictor. SDMs further revealed differences in climatic preferences between the three species. Temperature of the wettest quarter (BIO8) was important only for *B. aquilonaris* and *C. tullia*, and diurnal range (BIO2) only for *C. tullia* (Table 3).

SDM projections under current climate conditions revealed the largest predicted distribution in Western Europe for *B. aquilonaris* (1,426,977 km<sup>2</sup>), mainly in Scandinavia (Figure 5A). Its southern potential distribution was more fragmented on plateaus and mountains including very isolated patches. The two other species had a more restricted distribution. Climatically suitable areas for *C. tullia* (581,681 km<sup>2</sup>) were mainly located in Northern Europe, the UK, as well as few patches in the Alps and the Jura massif (Figure 5B). The last species *L. helle* (325,135 km<sup>2</sup>) had the smallest Scandinavian distribution, but encountered suitable areas in most of southern mountain ranges (Figure 5C). In the Jura massif, *B. aquilonaris* and *L. helle*

had similar predicted distributions composed of a large suitable area in high altitudes (> 900 masl), with a potential distribution range of 8,418 km<sup>2</sup> and 7,466 km<sup>2</sup>, respectively (Figures 5D and 5E). The predicted distribution range of *C. tullia* was reduced to 2,106 km<sup>2</sup> at altitudes <900m (Figure 5F).

### 3.5 Species past climate distribution

SDM projections under the eight paleoclimates revealed similar responses among the three species at the European scale (Figure 6A; Supplementary Figures S6 to S8). During the LIG, the distribution of climatically suitable areas included northern Europe and mountain chains, with a larger predicted distribution for *C. tullia* and *B. aquilonaris* than for *L. helle*. During the LGM, the projected distributions predicted an increase in habitat quantity for all species compared to LIG, but an increase in habitat quality only for *B. aquilonaris* and *L. helle*. This predicted geographic expansion was associated with a cooling of the climate and high values of isothermality overlapping well the species temperature requirements (Figure 6A). After the LGM, the quantity of habitats strongly decreased for all species, especially for *C. tullia* and *L. helle* whereas suitable habitats for *B. aquilonaris* were more abundant. Predicted habitat quality and quantity slightly increased since the late Holocene.

The changes in the quality and the quantity of habitats over time in the Jura massif were completely different from those observed at the European scale, with a decrease between LIG and HS similarly for the three species when the ice sheet covered a large area (Figure 6B). The changes in the distribution of climatically suitable areas over time were relatively similar for *B. aquilonaris* and *L. helle* (Figures 5D and 5F). During the LGM, the South of the Jura massif was covered by ice, which restricted the suitable areas for *B. aquilonaris* and *L. helle* in lowlands to the North of the massif. This LGM reduction of the distribution range was even more dramatic for *C. tullia*, with suitable areas only in the West of the massif (Figure 5E). Since

the HS period, the warming of the climate and ice retreat created new suitable habitats for *B. aquilonaris* and *L. helle*, which remained nearly constant until present days (Figures 5D, 5F and 6A). However, the projected distributions suggested an absence of suitable habitats for *C. tullia* in the Jura from the HS until the Mid Holocene (Figures 5E and 6A).

### 3.6 Effect of past climate changes on species demographic history

Our assessment of the impact of past climate fluctuations on the effective population size of peatland butterflies currently found in the Jura massif revealed two contrasting patterns between habitat quantity and quality. All the Spearman correlation tests between changes in the quantity of suitable habitats and  $N_e$  over time were non-significant for *B. aquilonaris* (Europe:  $\rho = 0.58$ ,  $P = 0.108$ ; Jura:  $\rho = -0.23$ ,  $P = 0.552$ ), for *C. tullia* (Europe:  $\rho = 0.17$ ,  $P = 0.678$ ; Jura:  $\rho = -0.12$ ,  $P = 0.764$ ) and *L. helle* (Europe:  $\rho = 0.60$ ,  $P = 0.097$ ; Jura:  $\rho = 0.09$ ,  $P = 0.814$ ). Although not all significant, we found positive relationships between changes in habitat quality and  $N_e$  over time at the European scale (*B. aquilonaris*:  $\rho = 0.62$ ,  $P = 0.076$ ; *C. tullia*:  $\rho = 0.63$ ,  $p = 0.068$ ; *L. helle*:  $\rho = 0.71$ ,  $P = 0.033$ ) but not in the Jura massif (*B. aquilonaris*:  $\rho = -0.02$ ,  $P = 0.982$ ; *C. tullia*:  $\rho = -0.04$ ,  $p = 0.931$ ; *L. helle*:  $\rho = -0.15$ ,  $P = 0.708$ ). The decrease in mean temperatures and increase in isothermality coincided with a reduction in  $N_e$  by 1.6 for the three species (Figures 4 and 6). Climatically suitable areas remained nearly stable (*B. aquilonaris*) or slightly increased (*C. tullia* and *L. helle*) between the end of the Holocene and current days (Figure 6). However, in the same period,  $N_e$  changes revealed dramatic population declines for *B. aquilonaris* (decrease factor  $\sim 47$ ) and *C. tullia* (decrease factor  $\sim 83$ ), and a decline of lower amplitude in *L. helle* (decrease factor  $\sim 3$ ).

## 4. Discussion

### 4.1 Same past history but different metapopulation functioning

The reconstructions of species demographic history show a common pattern of recent post-glacial population decline and fragmentation among the three species. Despite the ice covered most of their current range during the LGM, and habitat quality and quantity strongly varied at the Europe and Jura scales from the LIG to the Mid-Holocene (~6 kya), the effective population size remained nearly constant or only moderately decreased (by 1.6-fold) over this period (Figure 4). This suggests that the local populations have been able to track their thermal niche over time, probably by moving northward or upslope with glacier retreat (Figure 6; Supplementary Figures S6 to S8). Yet, our assessment of the effect of past climate changes on species demographic history revealed a positive relationship between the changes in habitat quality and the changes in effective population size over time at the European scale, which support a global-scale relationship between climate suitability and population size (Chattopadhyay et al., 2019). After the LGM, glacier retreat opened new habitats in northern Europe while the potential distribution of the three species progressively fragmented into small mountain areas in the South.

The Jura massif corresponds to one of the small areas at the warm range margin (Figures 5 and 6). Contrary to the general warming in many areas of Europe, the temperature continued to decrease in the Jura massif until 14–17 kya (Figure 5 and 6). During the LGM, the northern part of the massif was free of ice, with highly favorable habitats restricted to the margin of the ice sheet (Figure 5; Lhosmot et al., 2022). However, these habitats rapidly became less favorable for the presence of the three species, which might have partly moved their distribution further West. The lack of relationship between climate suitability and population size at the scale of the Jura massif supports the hypothesis that local populations shifted their distribution to track suitable habitats while maintaining nearly constant population size. Since 13–14 kya, the warming created new and more suitable habitats in the Jura massif for *B. aquilonaris* and *L. helle*, whereas habitat quantity and quality remained low elsewhere in Europe (Figure 6).

This result suggests that the Jura massif has provided a climatic refuge for these two species, but not for *C. tullia*, as habitat quality and quantity remained low until 6 kya. The North-to-South gradient of decreasing genetic diversity observed for *B. aquilonaris* and *C. tullia*, together with a more ancient divergence of populations in the northern region of the massif (RUS) common to all species, support a progressive re-colonization of the Jura massif from the northern deglaciated area. This confirms the position of the North of the Jura massif as a glacial refuge for boreo-montane butterflies (Sherpa et al., 2022). Finally, during the Holocene, we found an increase in habitat quality and quantity for all species, probably linked to the formation of peatlands in parallel with the progressive retreat of the Jura glaciers (from 5.8 to 12.9 kya; Gauthier et al., 2019; Lhosmot et al 2022). However, the three species kept declining during this period (Figures 4 and 6), which could reflect the influence of micro-climatic conditions and land uses by humans rather than global climate in recent times (Settele et al., 2008; Noreika et al., 2016).

The spatial distribution of genetic diversity reveals different metapopulation source-sink dynamics between species (Figure 2; Table 1; Supplementary Table S4). Contrary to *B. aquilonaris* and *C. tullia* (diverse pool in the North), the most diverse populations of *L. helle* are currently found in the central region of the massif (DDV; see also Habel et al., 2010), while the relictual northern populations are experiencing genetic erosion. Furthermore, populations of *C. tullia* and *L. helle* in this central region show high genetic connectivity, suggesting that the core of the metapopulation is shifting from RUS to DDV, which is confirmed by genetic differentiation indices ( $F_{ST}$ ) (Supplementary Table S6 and S8) and field estimates of population density (Duflo et al., 2017). Most populations are not at drift-migration equilibrium (positive population-specific  $F_{ST}$  and  $F_{IS}$ ). As the three species are short dispersers (Baguette, 2003; Gorbach, 2011; Turlure et al., 2014; Wainwright, 2005), small changes in the level of population connectivity can break down the metapopulation functioning, by reducing the

colonization probability of empty patches of habitat, and by increasing the extinction risk in highly isolated patches through genetic drift and inbreeding depression (Hansson, 1991; Hess, 1996; Gaggiotti, 2003; Perry and Lee, 2019).

#### 4.2 Close climatic niches but species-specific requirements

Species climate niche models reveal that the presence of *B. aquilonaris*, *C. tullia* and *L. helle* is determined by the same bioclimatic predictors, which can be explained by their common habitat requirements. These cold-adapted butterflies all live in cold and humid habitats, such as bogs, mires or their margins (Turlure et al., 2010; Habel et al., 2011; Weking et al., 2013). Accordingly, two common predictors of their geographic distribution include a low mean annual temperature ( $\text{BIO1} < 11^{\circ}\text{C}$ ) and a weak to moderate temperature variability within an average month relative to the year ( $\text{BIO3}$ ). Over their life cycle, the three species need a range of temperatures compatible with (1) the maintenance of soil water saturation for larval development, in relation to the ecology of their host-plants that grow on waterlogged soils (Čelik and Vreš, 2018; Goffart et al., 2014; Price et al., 1998; Schweingruber et al., 2020; Turlure et al., 2010), and (2) imagos thermoregulation activities during the flight period, essential for reproduction success (Kingsolver, 1983; Saastamoinen and Hanski, 2008). They are also equally constrained to areas with even precipitations throughout the year ( $\text{BIO15}$ ), required to maintain the hydrological quality of their habitat (Čelik and Vreš, 2018; Goffart et al., 2014; Turlure et al., 2013).

Each species occupies a slightly distinct climatic niche despite large overlap in temperature (70%) and precipitation seasonality (90%) ranges. For instance, mean temperature of the wettest quarter ( $\text{BIO8}$ ) was the third relevant predictor for the presence of *B. aquilonaris* and *C. tullia*. However, their niche is quite different (only ~40% of overlap) as *B. aquilonaris* tolerates more negative temperatures than *C. tullia* (Table 3), which can be explained by

differences in their biology and ecology. *B. aquilonaris* overwintering 1<sup>st</sup> instar caterpillars are buffered from negative temperature inside *Sphagnum* hummocks (Turlure et al., 2010; Turlure et al., 2013). In contrast, during flooding events, 3<sup>rd</sup> instar *C. tullia* caterpillars must actively climb up the stem of the host-plant (Joy and Pullin, 1997; Joy and Pullin, 1999), which requires temperature warm enough. The climatic niche of *C. tullia* also appears to be more constrained than the two other species, as five of the six variables used in SDMs contribute to its predicted distribution by more than 10% (Table 3). The geographic distribution of *C. tullia* excludes elevated areas (> 1,000 masl), where the mean diurnal temperature range is too high (BIO2 > 6°C). By contrast, *L. helle* overwinters as a pupa, with no less than 300 days spent at this stage. Pupal stage microclimatic requirements are not well known (Turlure et al., 2014) but our results suggest that it needs to be shielded from frost (Table 3). Such conditions are found under the vegetation litter where the last stage caterpillar shelters to pupate (Fisher et al., 2014). Out of the three species, *L. helle* is the most thermophilic (BIO1 > 0°C) and the less dependent on soil water saturation as its host-plant, *B. officinalis*, is widely distributed. Our demographic inferences also suggest that this species is the less vulnerable to habitat degradation and climate change, as its population has experienced much more limited decline as compared to the two other species.

The Jura massif constituted a thermal refuge for the three butterfly species during the last glacial cycle and continues in the current context of global warming. The massif included suitable areas for *B. aquilonaris* and *L. helle* over time since the LIG, suggesting they have persisted locally throughout the last glacial cycle (Figure 5). However, for *C. tullia*, local conditions were unfavorable from 17,0 to 4,2 kya (Figure 6). This species is currently found in the massif in fenlands mainly composed of *Carex spp.*, that are more abundant in warmer peatlands than in cold ombotrophic bogs characterized by plant community dominated by *Sphagnum spp.* (Dieleman et al., 2015). The formation of fenlands, which requires sufficiently

high temperature, were probably not encountered locally until the Mid-Holocene in the Jura massif, explaining that local conditions were unfavorable for *C. tullia*. Although the three species probably responded to Pleistocene climatic events by shifting their distribution, the improvement of climate conditions over the past 4,000 years in the Jura massif, and the associated increase in habitat availability, did not slow down the prolonged and ongoing decline of populations. Furthermore, they currently occupy habitats in which temperature conditions correspond to the upper limits of their respective thermal niches. Together, these results suggest that boreo-montane species are somehow trapped in isolated areas (south margin) and in their specific habitat (fragmented patches) (see also Sherpa et al., 2022). This implies that species might not be able to respond to future climate change, especially for dispersal-limited and habitat specialist species (Habel et al., 2023), and that further habitat degradation threaten the persistence of populations.

### 4.3 Conservation implications

The three species under study are not equally vulnerable to climate change. Based on population genomics analyses and ecological models, *C. tullia* appears to be more affected than *B. aquilonaris* and *L. helle*. Interestingly, their conservation status at the European scale ranks differently, in accordance to their predicted range in Europe: *L. helle* is classified by the IUCN (<https://www.iucnredlist.org>) as endangered (EN), *C. tullia* as vulnerable (VU) while *B. aquilonaris* is of least concern (LC). As one of the last areas sheltering *B. aquilonaris*, *C. tullia* and *L. helle* in South-Western Europe, the French Jura region is of priority concern. All species are currently experiencing a dramatic decline in this region, which justifies the integration of management measures into the national and regional action plans for their conservation (Houard and Jaulin, 2018; Jacquot et al., 2022).

Species conservation relies on two main axes: the restoration/improvement of habitat buffering against climate change and of landscape connectivity to ensure a dynamic metapopulation functioning (Bennett et al., 2021). In this context, the present multi-taxa study represents a major step towards a better knowledge on the evolutionary history, species-specific ecological requirements, and local dynamics of populations. The genetic erosion and geographic isolation of populations in the Jura massif make them particularly vulnerable to ongoing climate change. For instance, the karstic nature of the massif ground makes it more sensitive to droughts (Bidault et al., 1990). The repetition of dry summers these last years could strongly affect the hydrological equilibrium of the species habitats, and the vegetation structures protecting them from extreme temperatures during summer and winter. In addition to climate conditions, human activities and infrastructures development are other drivers of population trends, as peat cutting, the modification of waterbeds, and the installation of drainage systems to develop agriculture in the massif, which disturb bogs hydrological functioning and peat ecosystems (Gauthier et al., 2019). Indeed, the degradation of wetlands is well documented throughout Europe, due to increased global demand for land and water, pollution, and climate change. Their role as biodiversity hotspots and their contribution for many ecosystem services, such as carbon sequestration and climate change adaptation, stress an urgent need to protect and restore these fragile ecosystems (Kimmel and Mander, 2010; Joosten, 2015; Cartwright, 2019). Measures impeding global warming effects on the hydrological functioning of species habitat are essential, especially with the accumulation of drought events. Concrete solutions include avoidance of additional water withdrawals in peatlands by obliteration of drainage ditches and restoration of historical streambeds.

Our study, combining population genomics analyses and species distribution modeling, confirms the power of these approaches to provide valuable regional-scale recommendations for protecting species (Forester et al., 2013; Supple and Shapiro, 2018). First, genomics (as

opposed to genetics based on a few markers) is particularly precious in conservation biology that focuses on endangered species with low population sizes, because it allows low local sampling size. The low number of individuals collected per locality is compensated by the high number of loci genotyped: instead of averaging heterozygosity across individuals for a few markers to estimate genetic diversity, heterozygosity is averaged across loci, which allows a more precise (lower variance) estimation of local genetic diversity, even when only few individuals are sampled (Nazareno et al., 2017; Després et al., 2019). Contrary to global genetic parameters, the estimation of effective population size requires larger sample sizes, especially for recent demographic events (Robinson et al., 2014; Nunziata and Weisrock, 2018; McLaughlin and Winker, 2020). For this purpose, we considered the species-level (96 gene copies) estimates of site frequency spectrum to infer demographic dynamics, but we also show that robust inference can be obtained with smaller sample sizes (Figure S5). Second, we identify several groups of isolated populations suffering from drift and genetic erosion in the Jura massif, especially in the southernmost region where populations might be more vulnerable to extinction. Because the northernmost region harbors the highest population diversity for two of the studied species, conservation actions may focus on habitat restoration to maintain these diverse gene pools, and on improving landscape connectivity to allow migration to southern recipients. More precise management recommendations may arise from a fine scale study to identify functional ecological corridors (i.e., landscape factors that favor gene flow) and new or former suitable habitat patches for future colonization, which can guide population management (Savary et al., 2021; Osborne et al., 2022), especially improving landscape connectivity to promote the natural movement of species, which can be combined with the reinforcement or reintroduction of populations via assisted migration (Andersen et al., 2014; Descimon and Bachelard, 2014).

## 5. Conclusions

The use of genomics in conservation is still limited and usually tackles single species, which is only part of larger conservation activities aiming to restore and conserve entire habitats (Suchácková Bartonová et al., 2023). The analyses of population genomes and species distributions are powerful tools to better understand the genomic and demographic consequences of climate changes over time and to inform conservation decisions. By integrating the output of both approaches, our study sheds light not only on the current population dynamics, but also on the species abilities to respond to past climate changes, and therefore on their vulnerability to ongoing climate change. Furthermore, we determine that multiple co-distributed species have a shared demographic and biogeographic history, due to similar habitat and climate niche, and recolonization history. Such knowledge is essential to better predict community-scale responses to climate warming, and to implement conservation actions that can benefit multiple species. Nonetheless, we also found idiosyncratic responses to habitat fragmentation at the local scale, which might be explained by specific species traits and distinct metapopulation dynamics. This allows identifying the species that might be more vulnerable to extinction and areas that might act as diversity reservoirs. Incorporating our comparative approach with time series genomic data (Díez-del-Molino et al., 2018; Clark et al., 2023) can further help evaluating the effect of management practices on population connectivity and effective size over time, and/or identify source/sink populations for future reintroduction or reinforcement actions.

## Supplementary material

## Data accessibility

The ddRAD sequences (fastq) are available at the European Nucleotide Archive repository (<http://www.ebi.ac.uk/ena>) and accessible under study accession numbers PRJEB65448. The SNP datasets are available at Dryad Digital Repository (DOI: 10.5061/dryad.pk0p2ngt1). In accordance with the French regulation regarding protected species (article L.124-4 of the environment code), the precision of coordinates of the localities sampled in the Jura massif was degraded to 10 × 10 km uncertainty but are available from authors upon request. The GBIF occurrence datasets are available at <https://doi.org/10.15468/dl.3gc8xu> (*C. tullia*), <https://doi.org/10.15468/dl.cjnunz> (*B. aquilonaris*) and <https://doi.org/10.15468/dl.tbwmfm> (*L. helle*).

# Figures and figure captions

**Figure 1. Study area and location of sample sites for the three species.** The top left map shows the context of the study area, locating the Jura massif on the border between France (FR) and Switzerland (CH). The enlarged map shows the Jura massif with the three main study regions (HJ; RUS; DDV) in different transparent fill colors. Symbol shape and colors represent the location of sample sites for each species. Photos credits: *B. aquilonaris*, Frédéric Mora; *C. tullia*, Mathilde Poussin; *L. helle*, Pierre Durllet.

**Figure 2. Spatial patterns in genetic diversity.** A) Density and distribution of observed ( $H_o$ ) and expected ( $H_e$ ) heterozygosity (scaled and centered separately for each species) among the three regions, from North (RUS) to South (HJ). B) EEMS contour plots of the average posterior distribution of diversity rates  $q$  ( $\log_{10}$  scale). Darker font colors show significantly high (blue) or low (brown) within-deme genetic dissimilarities.

**Figure 3. Genetic differentiation among regions.** Average ancestry coefficients among individuals per sampling locality, estimated from ADMIXTURE analyses for A) *B. aquilonaris* (K = 3) B) *C. tullia* (K=4) and C) *L. helle* (K=6).

**Figure 4. Population demographic history.** A) Changes in effective population size ( $N_e$ ) over time based on the species-level SFS (all regions combined) using Stairway Plot v2. Full-colored lines: median  $N_e$ ; dotted lines: 95% confidence intervals (CI) generated from 200 bootstrap replicates (population-level analyses in Supplementary Figure S5). B) Schematic representation of the best divergence scenario for the three species using DIYABC (see Table 2 for identification of best scenario). C) Estimated divergence and decline times for the best scenario presented in B (posterior distributions for the 1% simulated data closest to the observed data).

**Figure 5. Changes in species potential distribution over time in the Jura massif.** Species potential distribution at the European scale based on six bioclim variables (BIO1, BIO2, BIO3, BIO8, BIO12, BIO15) under current conditions for A) *B. aquilonaris* B) *C. tullia* and C) *L. helle*. Predicted distributions under current climate (Cur) and palaeoclimates in the Jura massif (predicted distributions at the European scale are in Supplementary Figures S6 to S8) for D) *B. aquilonaris* E) *C. tullia* and F) *L. helle*. Paleoclimates (in kya): Late Holocene (LatH); Mid Holocene (MidH); Early Holocene (EarH); Younger Dryas Stadial (YDS); Bølling-Allerød (BA); Heinrich Stadial 1 (HS); Last Glacial Maximum (LGM); Last Interglacial (LIG).

**Figure 6. Changes in climate suitability over time in (A) Europe and (B) the Jura massif.**

From top to bottom: changes in habitat quantity (full line), in habitat quality (dashed line), and in climate conditions for the two temperature variables important for the current distribution of species: mean annual temperature (BIO1) and isothermality (BIO3) over the nine time periods considered. Cur: 1970–2000; LatH: 0.3–4.2 kya; MidH: 4.2–8.3 kya; EarH: 8.3–11.7 kya; YDS: 11.7–12.9 kya; BA: 12.9–14.7 kya; HS: 14.7–17.0 kya; LGM: 21 kya; LIG: 130 kya.

**Tables**

**Table 1. Regional genetic diversity.** Regions: Haut-Jura (HJ); Doubs-Druegon valleys (DDV); plateau of Russey (RUS); and their sample sizes (N). Diversity indices: observed heterozygosity (Ho); expected heterozygosity (He); inbreeding coefficient (F<sub>IS</sub>); population-specific differentiation (F<sub>ST</sub>). 95% confidence intervals (CIs) based on bootstraps of the data.

| Species               | Region | N   | Ho    |             | He    |             | F <sub>IS</sub> |             | F <sub>ST</sub> |             |

5 **Table 2. Identification of the best divergence scenarios between regions for each species.** Analysis 1 tested the period (ancient vs. recent) and  
 6 the mode (during increase vs. decrease in Ne) of divergence; all synchronous. Analysis 2 tested the simultaneous divergence of the three populations  
 7 or whether one population diverged first. Prior and posterior distributions of parameters are in supplementary Tables S3 and S5, respectively, and  
 8 schematic representation of split times and sequence in Figure 4B.

| Analysis 1. Period and factor of divergence |                     |                     |                     |                          |              |               |
|---------------------------------------------|---------------------|---------------------|---------------------|--------------------------|--------------|---------------|

9 **Table 3. Species climatic requirements.** For each of the six bioclim variables included in SDMs, the range is given for any variable having a  
 10 relative importance >10% and represents the range observed in predicted areas with high presence probability of the species (pp > ppTSS) at the  
 11 European scale and in the Jura massif. BIO1: Mean annual temperature; BIO2: Mean diurnal range; BIO3: isothermality; BIO8: mean temperature  
 12 of the wettest quarter; BIO12: annual precipitation; BIO15: precipitation seasonality.

| Bioclim variable | Relative importance   |                  |                 | Range of variable     |                  |                 | Western Europe        |                  |                 | Range of variable     |                  |                 | Jura massif |  |
